Abstract

Pathogenic variants in FBXL4 cause a severe encephalopathic syndrome associated with mtDNA depletion and deficient oxidative phosphorylation. To gain further insight into the enigmatic pathophysiology caused by FBXL4 deficiency, we generated homozygous Fbxl4 knockout mice and found that they display a predominant perinatal lethality. Surprisingly, the few surviving animals are apparently normal until the age of 8–12 months when they gradually develop signs of mitochondrial dysfunction and weight loss. One-year-old Fbxl4 knockouts show a global reduction in a variety of mitochondrial proteins and mtDNA depletion, whereas lysosomal proteins are upregulated. Fibroblasts from patients with FBXL4 deficiency and human Fbxl4 knockout cells also have reduced steady-state levels of mitochondrial proteins that can be attributed to increased mitochondrial turnover. Inhibition of lysosomal function in these cells reverses the mitochondrial phenotype, whereas proteasomal inhibition has no effect. Taken together, the results we present here show that FBXL4 prevents mitochondrial removal via autophagy and that loss of FBXL4 leads to decreased mitochondrial content and mitochondrial disease.

Introduction

Mitochondrial diseases are a heterogeneous group of inherited metabolic disorders characterized by deficient oxidative phosphorylation (OXPHOS) that leads to a variety of secondary metabolic defects and pleiotropic clinical phenotypes (Gorman et al, 2016). Mutations that cause mitochondrial disorders can be localized to either nuclear DNA or mtDNA and may affect a variety of mitochondrial processes such as mtDNA expression, biogenesis of the OXPHOS system, mitochondrial protein import, or mitochondrial dynamics. Although a given pathogenic mutation often is rare, the collective burden of such mutations is substantial, making mitochondrial diseases the most common form of inherited metabolic disorders.

In order to keep the mitochondrial population of the cell in shape, several quality control mechanisms act on mitochondria. These mechanisms include the cytosolic ubiquitin–proteasome system, several intramitochondrial proteolytic systems, autophagic clearance of damaged mitochondria, and the mitochondria-derived vesicle pathway (Bragoszewski et al, 2017; Zimmermann & Reichert, 2017; Pickles et al, 2018). Mutations in Parkin and PINK1 cause early-onset forms of Parkinson’s disease, and the corresponding proteins have been reported to be involved in mitochondrial protein control (Hauser & Hastings, 2013; Moon & Paek, 2015; Hernandez et al, 2016), but their in vivo roles remain controversial (Lee et al, 2018; Sliiter et al, 2018). Apart from PARKIN, other ubiquitin ligases, such as FBXO7, MARCH5, and HUWE1, have been related to mitochondrial quality control by directing proteins for proteasomal degradation or by triggering mitophagy (Chen et al, 2017; Di Rita et al, 2018; Zhou et al, 2018). Recently, ubiquitination has also been reported to occur in the inner mitochondrial membrane and this process may possibly contribute to fine-tune metabolism according to the energetic demand of the cell (Lavie et al, 2018).

FBXL4 is a nuclear gene that is implicated in control of mitochondrial function as biallelic mutations recently have been linked to encephalopathy associated with an mtDNA maintenance defect syndrome (Bonnen et al, 2013; Gai et al, 2013). The disease onset varies from the neonatal period to a few years after birth, and affected patients present a wide range of manifestations, including...
human cells, consistent with the hypothesis that increased autophagy rescues mitochondrial protein stability in content. Treatment with the lysosomal inhibitor ammonium chloride proteins and mitochondrial translation remained unaffected in the Surprisingly, expression of nuclear genes encoding mitochondrial FBXL4 derived from patients with loss-of-function mutations. Using proteomic analysis of the data confirmed a significant difference in the genotype distribution in the mice compared with the expected Mendelian ratios (P-value < 0.0001). Further analysis showed that there was an increased frequency of dead pups after birth although the exact frequency cannot be determined due to cannibalization by the mother. These findings show that most FBXL4−/− pups die in the neonatal period.

Patients with FBXL4 mutations display a significant reduction in mtDNA content (Bonnen et al., 2013; Gai et al., 2013), and we therefore measured the relative mtDNA copy number by quantitative real-time PCR (qRT–PCR). We found that homozygous knockout (FBXL4−/−) embryos at E13.5 had ~25% lower mtDNA content in comparison with wild-type embryos (Fig 1D). However, this moderate reduction in mtDNA copy number is unlikely to affect embryo viability because homozygous Tlam knockout mice are born at Mendelian ratios despite having ~50% reduction in mtDNA copy number (Larsson et al., 1998).

Surprisingly, the rare surviving FBXL4−/− animals looked apparently normal until 8–12 months of age when a reduction in body weight was noticed (Fig 1E and F). Most animals (~60%) also had a hunch-back appearance at this age (Fig 1E), and ~40% of animals had reduced movement, being apathetic or nervous when handled. At 1 year of age, a significant weight difference was observed in both males and females (Fig 1F). The absolute weights of heart, liver, and kidney were normal or near normal in FBXL4−/− females and males (Fig 1G–I), whereas organ-to-body weight ratios were

**Results**

*Fbxl4* knockout mice have high perinatal mortality

We generated mice with a conditional *Fbxl4* knockout allele and obtained heterozygous knockouts (*Fbxl4*+/−; Fig 1A) after breeding to β-actin-cre mice. We analyzed staged embryos at embryonic day (E) 13.5 and found that *Fbxl4*−/− embryos were recovered at near the expected Mendelian frequency (Fig 1B) and had a normal gross morphological appearance (Fig 1C). In contrast, very few homozygous knockout (*Fbxl4*−/−) mice were recovered at weaning (Fig 1B) pointing toward late embryonic or perinatal lethality. Chi-square analysis of the data confirmed a significant difference in the genotype distribution in the mice compared with the expected Mendelian ratios (**P**-value < 0.0001). Further analysis showed that there was an increased frequency of dead pups after birth although the exact frequency cannot be determined due to cannibalization by the mother. These findings show that most *Fbxl4*−/− pups die in the neonatal period.

Patients with *FBXL4* mutations display a significant reduction in mtDNA content (Bonnen et al., 2013; Gai et al., 2013), and we therefore measured the relative mtDNA copy number by quantitative real-time PCR (qRT–PCR). We found that homozygous knockout (*FBXL4*−/−) embryos at E13.5 had ~25% lower mtDNA content in comparison with wild-type embryos (Fig 1D). However, this moderate reduction in mtDNA copy number is unlikely to affect embryo viability because homozygous *Tlam* knockout mice are born at Mendelian ratios despite having ~50% reduction in mtDNA copy number (Larsson et al., 1998).

Surprisingly, the rare surviving *FBXL4*−/− animals looked apparently normal until 8–12 months of age when a reduction in body weight was noticed (Fig 1E and F). Most animals (~60%) also had a hunch-back appearance at this age (Fig 1E), and ~40% of animals had reduced movement, being apathetic or nervous when handled. At 1 year of age, a significant weight difference was observed in both males and females (Fig 1F). The absolute weights of heart, liver, and kidney were normal or near normal in *FBXL4*−/− females and males (Fig 1G–I), whereas organ-to-body weight ratios were
Figure 1.
significantly increased for most organs (Fig EV1A–C). Histological examination of organs of 1-year-old Fbxl4−/− animals showed no pathological alterations in the heart nor the kidney (Fig EV1D). However, we observed infiltration of macrophages in the liver, confirmed by Iba1 staining (Fig EV1E), pointing to tissue damage and degeneration. We did not observe differences in COX or sequential COX/SDH reactivities in skeletal muscle sections (Fig EV1F).

**Fbxl4 knockout mice have decreased levels of mtDNA and mitochondrial proteins**

Levels of mtDNA were significantly decreased in liver, kidney, and brain but not in heart and skeletal muscle of Fbxl4−/− mice at the age of 1 year (Fig 2A). Also, the mtDNA-encoded transcripts were significantly lower in all analyzed tissues, whereas the levels of nuclear transcripts remained mostly unaffected (Fig 2B).

The decrease in mtDNA and mtDNA-encoded transcripts can be due to a selective depletion of mtDNA or a general decrease in mitochondrial content in the tissue. To investigate this question, we determined the cellular content of mitochondrial proteins and the protein content of isolated mitochondria by using Western blot and mass spectrometry analyses (Figs 2C–F and EV2A–F). The steady-state levels of selected mitochondrial proteins, as determined by Western blotting, were strongly decreased in whole liver homogenates of Fbxl4−/− animals, irrespective of if they were encoded by mtDNA or nuclear DNA (Fig 2C). Tandem mass tag (TMT)-based mass spectrometry analysis of liver tissue homogenate confirmed a global, pathway-independent reduction in mitochondrial proteins, whereas there was an enrichment of lysosomal proteins, such as cathepsins (Ctsb, Ctsc, Ctsd, Ctsl) and other hydrolases (Fig 2E and F, and Dataset EV1). A total of 83 proteins showed significant changes, 57 of which were downregulated and 26 upregulated in homogenate from whole Fbxl4−/− liver (Fig 2E and Dataset EV1). In contrast, label-free, global proteomic analyses of isolated mitochondria from liver, kidney, and heart showed only mild changes in the proteome affecting, e.g., amino acid degradation pathways and propanoate metabolism, consistently with mild metabolic derangement in Fbxl4−/− mitochondria. Importantly, we found no changes in the expression of nuclear-encoded proteins controlling mtDNA maintenance. Analysis of selected proteins by Western blots confirmed the results from proteomics (Fig EV2B, D and F).

The proteomic changes displayed a strong tissue specificity with only six proteins (Pgam5, Grhpr, Acsm5, Spr, Nmat3, and Nii2) consistently changed in mitochondria from all three analyzed tissues (Fig EV2G and Dataset EV2). Kidney and liver, the most affected organs, had 52 commonly changed proteins, mostly belonging to mitochondrial metabolic enzymes and not related to mtDNA maintenance and expression (Dataset EV2).

We proceeded to assess the assembly of OXPHOS complexes in Fbxl4 knockout mice by resolving respiratory chain complexes from liver mitochondria with blue native polyacrylamide gel electrophoresis (BN–PAGE) followed by in-gel enzyme activity staining for complexes I and IV, and Coomassie staining (Fig EV2H). Despite reduced amounts of the OXPHOS complexes, consistent with reduced steady-state respiratory chain protein levels, no aberrantly assembled or unassembled subcomplexes were observed. In agreement with the BN–PAGE data, spectrophotometric measurement of OXPHOS complex enzyme activities in liver mitochondria did not show major alterations, except a mild, but significant, decrease in complex IV activity (Fig EV2I). Overall, these results are in line with the hypothesis that the mitochondrial dysfunction in Fbxl4−/− animals is predominantly due to reduced cellular mitochondrial content likely through turnover by lysosomes.

**Altering in patient fibroblasts are similar to the changes in knockout animals**

To investigate whether the findings in Fbxl4−/− mice are relevant for the human disease, we characterized fibroblasts obtained from skin biopsies of three patients homozygous for recessive Fbxl4 mutations (Fig 3A) and three age-matched healthy controls. Patient 1 and Patient 2 have been published previously (Bonnen et al, 2013) and harbor homozygous Fbxl4 mutations, p.Arg435* and p.Gln519*, respectively (GenBank Accession Number: NM 012160.3). Patient 3 was diagnosed at Karolinska University Hospital and is a compound heterozygote for two independently segregating Fbxl4 mutations, p.Arg22* on one allele and p.Arg206* on the other allele.

Fbxl4-deficient fibroblasts had lower mtDNA content compared with age-matched control fibroblasts (Fig 3B), in line with previously published findings (Bonnen et al, 2013; Gai et al, 2013). The levels of mitochondrial proteins were also significantly lower in patient-derived fibroblasts compared with controls, both for mtDNA- and nuclear-encoded proteins (Fig 3C and D). Importantly,
levels of mtDNA-encoded transcripts were decreased, whereas levels of nuclear transcripts encoding mitochondrial proteins were present at normal levels (Fig 3E). The global reduction in mitochondrial protein levels is thus explained by post-transcriptional events rather than by differences in nuclear gene expression.

Tandem mass tag-based quantitative proteomic analysis of patient fibroblasts showed a clear trend with downregulation of many mitochondrial proteins (Fig 3F), which is in good agreement with the Western blot results (Fig 3C). Importantly, FBXL4-deficient fibroblasts have a mild increase in levels of lysosomal proteins.
Figure 3.
Decreased protein stability in FBXL4 datasets (Fig 3G). The increase in levels of lysosomal proteins due to alterations in lysosomal morphology were observed in confocal images of Lamp2-stained cells (Fig EV3A). Moreover, we did not observe any significant change in LysoSensor Green DND-189 fluorescence intensity (Fig EV3B). Based on the observation of increased levels of lysosomal proteins in mouse liver and patient fibroblasts lacking FBXL4 (Figs 2E and F, and 3C and D) concomitant with unaffected lysosomal pH (Fig EV3B), we conclude that increased lysosomal mass is increasing mitochondrial turnover.

These findings point toward a conserved mechanism whereby loss of FBXL4 in humans and mice leads to low levels of mitochondrial proteins, as demonstrated by the correlation of both proteomic datasets (Fig 3G). The increase in levels of lysosomal proteins induced by loss of FBXL4 was more marked in mouse tissues than in cultured human fibroblasts (Fig 3G). To summarize, the overall molecular phenotypes in whole tissue/cell extracts of FBXL4-deficient mice and human fibroblasts showed many similarities with low mtDNA levels, low levels of mitochondrial proteins, and increased levels of lysosomal proteins.

Decreased protein stability in FBXL4 knockout cells

We generated an FBXL4 knockout RKO cell line by CRISPR/Cas9-mediated gene disruption to get further insights into the role of FBXL4 in a defined cell culture system. The resulting clone had a 20-bp-long deletion in exon 4 of the FBXL4 gene, leading to a frameshift mutation and a stop codon in the open reading frame (Fig 4A).

The levels of mitochondrial proteins were reduced in the FBXL4 knockout cell line, similar to the findings in FBXL4 mutant patient fibroblasts (Fig 4B). To distinguish whether the altered levels of mitochondrial proteins were due to alterations in their biogenesis or degradation, we performed 35S labeling to study protein synthesis followed by a 16- to 24-h chase to monitor protein stability (Fig 4C). Mitochondrial translation was not affected in the knockout cell line, whereas the amounts of labeled products were significantly reduced after a 24-h chase, indicating an increased turnover of the newly synthesized proteins in the absence of FBXL4.

Given that FBXL4 is an F-box protein suggested to play a role in proteasomal degradation of proteins, we investigated whether inhibition of proteasomal activity could rescue the observed phenotype. To this end, we performed 35S labeling of cellular translation products and added the proteasomal inhibitor epoxomicin during the chase phase of the experiment. Epoxomicin treatment increased the differences in protein stability between wild-type and knockout cells and thus promoted increased mitochondrial protein turnover (Fig 4D). In contrast, treatment with the lysosomal inhibitor ammonium chloride rescued the phenotype seen during the chase phase of the cellular in vitro translation experiment (Fig 4D).

Further analyses showed that LC3-II, p62/SQSTM1, and ubiquitin conjugates accumulated to the same extent in both wild-type and FBXL4 KO cells after treatment with the lysosomal inhibitor NH4Cl, as well as after treatment with the proteasomal inhibitor epoxomicin (Fig 4E and F).

Fibroblasts from FBXL4-deficient patients show increased mitophagy

In order to further investigate the increased mitochondrial turnover in the different patient fibroblast lines, we introduced a mito-QC construct using a retroviral vector. Mito-QC is a GFP-mCherry construct targeted to the mitochondria that allow the in vivo analysis of mitophagy (Allen et al, 2013; McWilliams et al, 2016). In the mitochondria, both proteins are fluorescent, but upon internalization in the lysosome the low pH quenches GFP fluorescence but not mCherry.

We analyzed patient fibroblast and a control line using confocal microscopy and observed a mild but significant increase in the number of mitolysosomes/cell area (μm²) in the patient lines when compared to the control line expressing mito-QC (Fig 5A and B). These results support the conclusion that pathogenic FBXL4 variants lead to an increased mitochondrial turnover and, consequently, mitochondrial dysfunction.

Next, we explored the autophagic flux in the patient fibroblast lines by monitoring LC3 conversion and p62 protein levels. We grew the cells in medium without FBS for 3 h and thereafter added NH4Cl to block lysosomal function. As observed in the FBXL4 KO cells, no differences were found in the LC3-II or p62 levels between control and patient fibroblast lines (Fig EV4A–D). The findings indicate normal autophagic flux and suggest that the increased mitochondrial turnover is dependent on an alternate pathway not involving LC3 conversion. We also checked the accumulation of ubiquitin, p62, and LC3 in sucrose-purified mitochondria (Fig EV4E and F).
Figure 4.
No significant changes were found, supporting the suggestion of activation of an alternate pathway for mitochondrial turnover in the absence of Fbxl4.

In summary, we conclude that the increased mitochondrial protein turnover seen in FBXL4 deficiency is due to increased lysosomal degradation, likely via an alternative autophagy.
pathway, and is not explained by increased proteasomal activity. Furthermore, inhibition of lysosomal function rescues the mitochondrial protein stability phenotype in FBXL4 deficiency, suggesting that decreasing autophagy may be a strategy for the treatment of affected patients.

Discussion

The pathophysiology of human FBXL4 deficiency causing an encephalopathic syndrome associated with mtDNA depletion has remained enigmatic. Here, we present evidence that FBXL4 acts as a regulator preventing excessive turnover of mitochondria via lysosomes. We have characterized Fbxl4 knockout mice, FBXL4-deficient patient fibroblast, and a human FBXL4 knockout cell line and report several lines of evidence showing that loss of FBXL4 leads to increased mitochondrial turnover via lysosomes.

Quantitative proteomics showed an overall decrease in mitochondrial content and an increase in lysosomal proteins both in mouse tissues and in human fibroblasts lacking FBXL4. These results led us to hypothesize that mitochondrial content was decreased due to increased lysosomal degradation. This assumption was supported by 35S labeling experiments, which showed that mitochondrial protein stability in FBXL4 knockout cells was reduced but could be rescued by inhibiting lysosomal hydrolyses with ammonium chloride. In further support of the hypothesis, the mito-QC expression in patient fibroblasts showed an increased number of mitolysosomes consistent with increased mitochondrial turnover. However, the levels of LC3-II and also p62, a global autophagy marker (Calvo-Garrido et al., 2019), were similar in wild-type and FBXL4 knockout cells, also there was no difference in levels of these proteins in control and FBXL4 mutant human fibroblast lines. This finding can be explained by an alternative autophagy pathway that is independent of LC3. Such a pathway has been reported in Atg5 knockout mice and is dependent on the Rab GTPase, Rab9a (Kuma et al., 2004). This pathway involves the participation of vesicles from the trans-Golgi that engulf the cargos for subsequent fusion with lysosomes (Kuma et al., 2004). There is increasing evidence that Rab GTPases play an important role during autophagy and several members of this protein family have been related to different steps in the autophagy process (Ao et al., 2014). Interestingly, a slight increase in different Rab GTPases was observed in both mouse and human fibroblasts lacking FBXL4, including Rab9a in the case of human fibroblasts, which lends support to the hypothesis of the existence of an alternate autophagy pathway driven by this group of proteins. Another option that cannot be excluded is a role for the MDV pathway which is also independent of LC3 conversion (Sugiuira et al., 2014).

As we did not observe changes in the conversion of LC3-I to LC3-II, we assume that the classical pathway for autophagic flux in FBXL4-deficient cells is not affected. Instead, an alternate autophagy pathway may be upregulated leading to increased mitochondrial removal. This model seemingly contradicts the proposed role of FBXL4 as an F-box protein in the SCF complex. One possible explanation for this apparent discrepancy implies an important role for FBXL4 in mitochondrial quality control as a substrate-recognizing subunit of the ubiquitin ligase complex.

Consistent with this model, the absence of FBXL4 would lead to accumulation of aberrant mitochondrial proteins that could affect mitochondrial function and thus increase the degradation of mitochondria by the lysosome. However, there is no evidence showing the presence of the SCF complex in mitochondria and it is therefore unlikely that ubiquitination could happen in the mitochondrial intermembrane space (IMS) via FBXL4. Recently, it has been reported that ubiquitination could occur in the inner mitochondrial membrane, but the ubiquitin ligases or complexes catalyzing this reaction have not been identified (Lavie et al., 2018). Another possibility, although perhaps also unlikely, is that FBXL4 could recognize unfolded or damaged proteins in the IMS and promote their export to the cytosol for degradation. A somewhat similar mechanism has been shown in yeast, in which unfolded proteins can be retro-translocated from the IMS to the cytosol through the TOM complex and further degraded by the ubiquitin–proteasomal system in the cytosol (Bragoszewski et al., 2015).

The phenotypes of Fbxl4−/− mice agree with the alternate autophagy pathway model. The finding that Fbxl4−/− embryos are present at Mendelian ratios and develop normally until E13.5 despite having somewhat lower mtDNA levels argues that the mitochondrial phenotype is not the leading cause of the perinatal death. It should be pointed out that neonatal lethality has been reported in many autophagy-deficient animals, e.g., Atg3, Atg5, Atg7, and Atg12 knockouts (Kuma et al., 2004, 2017; Mizushima & Levine, 2010). Interestingly, Atg4b knockout mice were reported to be born at non-Mendelian ratios, but developed almost normally after birth, demonstrating a striking similarity to the Fbxl4−/− phenotype (Read et al., 2011). Although Fbxl4 knockout animals are not autophagy-deficient, we assume that increased mitophagy flux at birth could imbalance the overall autophagic states of the cell leading to mitochondrial deficiency. The decreased mitochondrial content caused by increased autophagic removal likely has a particularly deleterious impact in the neonatal period as it may prevent the crucial metabolic switch from glycolysis to OXPHOS in newborn animals. The few newborn FBXL4-deficient animals that survive this critical period will develop a slowly progressive mitochondrial phenotype much later in life.

In summary, the results we present here argue that the molecular phenotypes in FBXL4-deficient patients are explained by a global decrease in mitochondrial content and not by a specific role for FBXL4 in mtDNA maintenance or biogenesis of the OXPHOS complexes. Importantly, the finding that inhibition of lysosomal function can rescue molecular phenotypes in FBXL4-deficient cells suggests that manipulation of mitochondrial clearance by autophagy may be utilized as a future strategy to develop treatments of affected patients.

Materials and Methods

Fbxl4 knockout mice

Fbxl4 knockout mice were generated by Taconic Artemis by targeting the gene in embryonic stem cells derived from C57BL/6N using a vector from the C57BL/6J RPCI-23 BAC library. To generate the Fbxl4 knockout allele, exon 4 was flanked by loxP sites, and a
puromycin resistance (PuroR) cassette flanked by Frt sites was also introduced as a selection marker. The puromycin resistance cassette was removed by crossing Fbxl4+/loxP-Puro mice with mice expressing Flp recombinase. Fbxl4+/loxP mice were thereafter mated with mice ubiquitously expressing Cre recombinase (β-actin-cre) to generate heterozygous Fbxl4 knockouts. Finally, intercrosses of heterozygous knockout animals were performed to generate Fbxl4 knockout animals (Fbxl4−/−). Animals were housed in standard ventilated cages at 12-h light/dark cycle and fed with a normal chow diet ad libitum. For isolation of tissues, animals were sacrificed by cervical dislocation and dissected immediately. Isolated organs were snap-frozen in liquid nitrogen and stored at −80°C. Animal studies were approved by the animal welfare ethics committee and performed in compliance with European law.

Histology

For heart, kidney, and liver microscopy analyses, tissues were fixed in 4% PFA, dehydrated, and paraffin-embedded. Sections of 5 μm in thickness were mounted on glass slides, de-paraffinized with xylene, and stained with hematoxylin and eosin.

Immunohistochemical analysis

Liver sections were de-paraffinized with xylene and rehydrated by successive incubations in ethanol 100, 95, and 70% and water. Thereafter, slides were incubated in 10 mM sodium citrate buffer (pH 6) at sub-boiling temperature for 10 min and cooled at room temperature for 30 min. Before staining, slides were washed three times with water and incubated in 3% hydrogen peroxide for 10 min to quench endogenous peroxidase activity and washed twice in water. Thereafter, slides were blocked in 5% goat serum in TBST. Iba1 primary antibody (Wako) was used to detect Iba1 expression. Later, we used the VectaStain ABC HRP Kit (Vector Labs) and diaminobenzidine to detect immunoreactivity. Finally, slides were counter-stained with hematoxylin, dehydrated, and mounted for bright-field microscopy.

Sequential COX/SDH histochemistry

COX/SDH histochemistry was performed as previously described (Filograna et al., 2019). Briefly, quadriceps from wild-type and Fbxl4 knockout animals were washed in PBS and frozen in liquid nitrogen-cooled isopentane. Sections, 14 μm, were mounted in poly-lysine-coated glass slides and left air-dry briefly. Sections were incubated for 45 min at 37°C in COX medium (100 μM cytochrome c, 4 mM dianaminobenidine tetrahydrochloride, catalase (20 μg/mL), and 0.2 M phosphate buffer [pH 7]). Next, slides were washed in PBS and incubated for 30 min at 37°C in SDH medium (130 mM sodium succinate, 200 μM phenazinemethosulphol, 1 mM sodium azide, 1.5 mM nitroblue tetrazolium, and 0.2 M phosphate buffer [pH 7]). Finally, slides were washed in PBS, dehydrated in increasing ethanol concentrations, and mounted for bright-field microscopy.

RNA extraction and gene expression analysis

RNA from mouse tissues or cells was extracted using TRIzol Reagent (Invitrogen) following the manufacturer’s instructions. Total RNA (1 μg) was converted to cDNA using the High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems), and 10 ng of cDNA was used in each qPCR. These reactions were done with TaqMan Universal MasterMix (Applied Biosystems) in a QuantStudio 6 Flex (Applied Biosystems). Specific primers and probes were purchased from Applied Biosystems (TaqMan gene expression assays). The acquired data were analyzed with QuantStudio Real-Time PCR Software (v1.1). Relative expression was calculated based on Ct values for each gene normalized with the values obtained for housekeeping genes (Actb, B2M, or 18S ribosomal RNA). All probes used in this study are listed in Appendix Table S1.

DNA extraction and mtDNA quantification

Total DNA was isolated with standard phenol/chloroform and proteinase K digestion protocol, and the concentration was measured with Qubit DNA assay (Thermo Fisher Scientific). Quantitative PCR was performed to quantify mtDNA, using 5 ng of total DNA in each reaction. Specific probes for ND1 (mouse) or ND6 (human) were used to detect mtDNA, whereas the Actb probe (for mouse) or the 18S ribosomal RNA probe (for human DNA) was used to detect nuclear DNA. The relative mtDNA levels were calculated as the ratio of mtDNA/nDNA based on the obtained Ct values.

Cell culture

Mammalian cells were cultured in DMEM GlutaMax (Invitrogen) medium supplemented with 10% fetal bovine serum (FBS) and 1× PenStrep. Cells were grown in an incubator at 37°C in a 5% CO2 atmosphere. Patient fibroblasts lines 1 (p.Arg435*) and 2 (p.Gln519*) both harbor pathogenic, homozygous loss-of-function Fbxl4 mutations and were previously described in Bonnen et al., 2013 (S2 and S1, respectively, in the original report) (Bonnen et al., 2013). Patient fibroblast line 3 was obtained from a patient diagnosed at Karolinska University Hospital. Whole-genome sequencing of this patient identified two previously unreported heterozygous independently segregating stop mutations c.64C>T, p.Arg22* and c.616C>T, p.Arg206* in the Fbxl4 gene. The patient had widened lateral ventricles of the brain on intrauterine ultrasound screening, but showed no symptoms until 6 months of age when delayed motor development and general hypotonia became evident. At this age, the patient also had hyperlactatemia (p-lactate 6.5 mmol/l), hypochromic anemia, and neutropenia. Organic acids in urine showed elevated lactate, fumarate, and malate. There was decreased ATP synthesis, and the activities of OXPHOS complexes I, I + III, II + III and IV were reduced in isolated muscle mitochondria. Control fibroblasts used in this study were obtained from age-matched healthy individuals. Informed consent for research studies was obtained for all subjects or their parents and for controls in accordance with the Declaration of Helsinki protocols, the Department of Health and Human Services Belmont Report, and approved by the Regional Ethics Committee at Karolinska Institutet in Stockholm, Sweden.

The Fbxl4 CRISPR knockout cell line was generated as previously described (Ran et al., 2013). Briefly, a DNA sequence encoding a gRNA targeting Fbxl4 exon 4 was cloned into the pX459v2 vector. The RKO cell line (ATCC) was transfected with this vector using Lipofectamine 3000 (Thermo Fisher Scientific) following the
manufacturer’s recommendations. Transfected cells were selected with puromycin, and obtained clones were sequenced to analyze disruption of the FBXL4 gene.

Immunofluorescence

For Lamp2 immunofluorescence, cells were grown on glass coverslips. Coverslips were washed twice with PBS and fixed with 4% PFA in PBS for 15 min. After, cells were incubated for 1 h in 1% BSA, and 0.1% saponin in PBS. Cells were then incubated with Lamp2 antibody (Abcam) in 1% BSA, and 0.1% saponin in PBS at 4°C overnight. Coverslips were washed two times with PBS and then incubated with Alexa 568 anti-mouse secondary antibody for 1 h at room temperature. Finally, coverslips were stained with DAPI, washed five times with PBS, and mounted using Prolong Diamond Antifade Mountant (Life Technologies). The slides were imaged in a Zeiss LSM700 confocal microscope.

LysoSensor Green fluorescence measurement

A total of 1,000 cells were plated in black p96 well plates and allowed to attach. Thereafter, the medium was replaced with DMEM with 2 μM LysoSensor Green DND-189 (Life Technologies) and cells were incubated at 37°C for 30 min. Finally, cells were washed twice with PBS and fluorescence was immediately measured in a Tecan Infinite M200 Pro (Tecan). A total of five technical replicates were done for each line, and in each technical replicate, at least three wells per line were measured.

Mito-QC expression, imaging, and analysis

Mito-QC pBabe vector was kindly provided by Dr. Ian Ganley. Transfection of fibroblast lines was done as previously described (Allen et al., 2013). Cells stably expressing mito-QC were plated on glass coverslips. Coverslips were washed with PBS and fixed with 4% PFA, and 200 mM HEPES-KOH pH = 7 for 15 min and washed twice with PBS. Coverslips were mounted using Prolong Diamond Antifade Mountant (Life Technologies) and imaged in a Zeiss LSM700 confocal microscope. Obtained images were analyzed using the ImageJ mito-QC counter semi-automated tool (Montava-Garriga et al., 2020). Ratio threshold was set to 0.6, radius for smoothing = 1, and standard deviation over mCherry mean intensity = 3. At least three technical replicates were done for each line and >15 cells analyzed in each replicate.

Preparation of pure mitochondrial fractions

Pure mitochondrial fractions were obtained as previously reported (Kühl et al., 2017). Briefly, crude mitochondrial fractions were isolated from mouse liver, kidney, and heart using differential centrifugation procedures. The crude mitochondrial pellets were washed in 1xM buffer containing 220 mM mannitol, 70 mM sucrose, 5 mM HEPES ph = 7.4, and 1 mM EGTA, and thereafter, mitochondria were purified in a Percoll gradient (12–19–40%) through centrifugation in a SW41 rotor at 42,000 g at 4°C for 30 min in a Beckman Coulter Optima L-100 XP ultracentrifuge. Mitochondria were collected between 19 and 40% phases, and washed three times with 1xM buffer. Mitochondrial pellets were frozen at −80°C.

SDS–PAGE, BN–PAGE, and Western blotting

The protein content of samples was measured by Pierce™ BCA Protein Assay Kit (Thermo Fisher Scientific), and equal protein amounts were loaded on a gel. For SDS–PAGE, precast Bolt Bis-Tris Plus Gels (Thermo Fisher Scientific) were used according to manufacturer’s instructions. For Western blot analysis, the gels were blotted and membranes probed with antibodies of interest. Signal detection was done using HRP-coupled secondary antibodies with enhanced chemiluminescence substrate (Bio-Rad). A list of the used primary antibodies is provided in Appendix Table S2.

BN–PAGE was performed using the NativePAGE system (Thermo Fisher Scientific). In brief, 75 μg of mitochondria was solubilized in solubilization buffer: 1% (w/v) digitonin, 20 mM Tris–HCl pH 7.4, 0.1 mM EDTA, 50 mM NaCl, and 10% glycerol (v/v). After 10 min of incubation on ice, samples were centrifuged to eliminate non-solubilized material and supernatant was mixed with 5% w/v Coomassie Brilliant Blue G-250. Samples were separated in Native-PAGE 3–12% Bis-Tris gels (Thermo Fisher Scientific) followed by staining with Imperial Staining (Thermo Fisher Scientific) or in-gel complex activity staining as described previously (Matic et al., 2018). For complex I staining, gels were soaked in Tris–HCl pH 7.4 buffer containing 0.1 mg/ml NADH and 2.5 mg/ml iodotetrazolium chloride. For complex IV staining, gels were soaked in 50 mM phosphate buffer pH 7.4 with 0.5 M sucrose, 0.5 mg/ml 3,3’-diaminobenzidine tetrahydrochloride, 1 mg/ml cytochrome c, and 20 μg/ml catalase.

Biochemical assessment of OXPHOS enzyme activities

For the determination of OXPHOS biochemical activities, we used pure mitochondria isolated from liver. Protein concentration from Percoll purified mitochondria fractions was determined using Pierce™ BCA Protein Assay Kit (Thermo Fisher Scientific) and resuspended in a buffer containing 250 mM sucrose, 15 mM magnesium acetate, 2 mM EDTA, 0.5 g/l BSA, and 15 mM potassium dihydrogen phosphate pH = 7.2. Biochemical activities of the respiratory chain complexes were determined spectrophotometrically with standard methods as previously described (Wibom et al., 2002).

35S labeling of translation products in cells

Labeling of mitochondrial translation products with 35S-methionine was performed as described previously (Chomyn, 1996). Cells were grown in 24-well plates, extensively washed with PBS, and pre-incubated in Cys-Met-free DMEM medium (Gibco) for 20 min. Next, the cells were treated for 20 min with 100 μg/ml anisomycin (Sigma) to block cytosolic translation, and 3.7 MBq of 35S-l-methionine and cysteine mix (PerkinElmer) was added to the cells for 60 min to label newly synthesized mitochondrial translation products. For the chase experiment, cells were extensively washed with PBS and complete DMEM + FBS medium to remove radioactive substances and anisomycin, and then grown for 16–24 h. The radiolabelled translation products were resolved by SDS–PAGE, and the gels were dried and exposed to phosphor screens for radioactive signal detection.
**Protein extraction, proteolytic digestion, and chemical labeling**

Cell pellet samples were suspended in a mixture of 0.1% ProteaseMax (Promega), 4 M urea (Sigma-Aldrich), 50 mM ammonium bicarbonate, and 10% acetonitrile (AcN), and were sonicated with a VibraCell probe (Sonic & Materials, Inc.) for 1 min, with pulse 2/2, at 20% amplitude. Following sonication in a water bath for 5 min, extracts were vortexed and centrifuged for 5 min at 16,000 g. The supernatants were thereafter transferred to new tubes, and protein concentrations were determined in a 1:10 dilution with water yielding 500–1,300 μg protein (mouse fibroblasts).

Tryptic digestion with an enzyme-to-protein ratio of 1:50 was performed with 25 μg of each sample using a protocol including reduction in 6 mM dithiothreitol at 37°C for 60 min, alkylation in 22 mM iodoacetamide for 30 min at room temperature in the dark, and proteolysis overnight at 37°C. Tryptic peptides were cleaned with C18 HyperSep Filter Plate, bed volume 40 μl (Thermo Fisher Scientific), and dried on a SpeedVac (mVac, Thermo Fisher Scientific). Six of TMT10plex reagents (Thermo Fisher Scientific) in 100 μg aliquots were dissolved in 30 μl dry AcN, scrambled, and mixed with the digested samples dissolved in 70 μl TEAB (resulting in final 30% AcN), followed by incubation at 22°C for 2 h at 550 rpm. The reaction was then quenched with 12 μl of 5% hydroxylamine at 22°C for 15 min at 550 rpm. Finally, the labeled samples were pooled and dried in a SpeedVac.

Enriched mitochondria were lysed in 6 M guanidinium chloride, 10 mM Tris–HCl, 40 mM chloroacetamide, and 100 mM Tris–HCl by heating the solution at 95°C for 10 min, followed by repeated cycles of sonication for 10 and 30 s and a 30-second pause on a Bioruptor (Diagenode). Samples were centrifuged for 20 min at 20,000 g, and the supernatant was diluted 1:10 using 20 mM Tris–HCl pH 8. Overnight digestion was done using 1 μg Trypsin Gold (Promega) at 37°C. The supernatant was acidified with 5% formic acid, and the solution was desalted using home-made StageTips (Rappsilber et al, 2003).

**Liquid chromatography–tandem mass spectrometry**

Samples, 2 μg aliquots, were injected into a 50-cm-long C18 EASY spray column (Thermo Fisher Scientific) installed in a nano-LC-1000 system online coupled to an Orbitrap Fusion mass spectrometer (Thermo Fisher Scientific, Bremen, Germany). The chromatographic separation of the peptides was achieved with the organic gradient as follows: 2–26% AcN in 110 min, 26–35% AcN in 10 min, 35–95% AcN in 5 min, and 95% AcN for 15 min at a flow rate of 300 nl/min. Full mass scans were acquired in m/z 375–1,500 at a resolution of R = 120,000 (at m/z 200), followed by data-dependent HCD fragmentations from maximum 15 most intense precursor ions with a charge state 2+ to 7+. The tandem mass scans were acquired with a resolution of R = 60,000, targeting 5 × 10^4 ions, setting isolation width to m/z 1.4, and normalized collision energy to 35%.

For label-free proteomic analysis, peptides were separated on a 25-cm, 75-μm internal diameter PicoFrit analytical column (New Objective) packed with 1.9 μm ReproSil-Pur 120 C18-AQ media (Dr. Maisch,) using an EASY-nLC 1200 (Thermo Fisher Scientific). The column was maintained at 50°C. Buffer A and buffer B were 0.1% formic acid in water and 0.1% formic acid in 80% acetonitrile. Peptides were separated on a segmented gradient from 6 to 25% buffer B for 135 min, from 25 to 31% for 20 min, and from 31 to 50% buffer B for 20 min at 200 nl/min. Eluting peptides were analyzed on a QExactive HF (Thermo Fisher Scientific). Peptide precursor m/z measurements were carried out at 60,000 resolution in the 300–1,800 m/z range. The ten most intense precursors with charge state from 2 to 7 only were selected for HCD fragmentation using 25% normalized collision energy. The m/z values of the peptide fragments were measured in the Orbitrap at 30,000 resolution, using a minimum AGC target of 8e3 and 55-ms maximum injection time. Upon fragmentation, precursors were put on a dynamic exclusion list for 45 s.

**Protein identification and quantification**

Acquired raw data files were loaded in Proteome Discoverer v2.2 and searched against mouse or human SwissProt protein databases (42,793 and 21,008 entries, respectively) using the Mascot 2.5.1 search engine (Matrix Science Ltd.). A maximum of two missed cleavage sites were allowed for trypsin, while setting the precursor and the fragment ion mass tolerance to 10 ppm and 0.05, respectively. Dynamic modifications of oxidation on methionine, deamidation of asparagine and glutamine, and acetylation of N-termini were set. For quantification, both unique and razor peptides were requested. The final quantitative data analysis was performed with an in-house developed R script.

Label-free proteomic data were analyzed with MaxQuant version 1.6.1.0 (Cox & Mann, 2008) using the integrated Andromeda search engine (Cox et al, 2011). Peptide fragmentation spectra were searched against the canonical and isofrom sequences of the mouse reference proteome (proteome ID UP000000589, downloaded in September 2018 from UniProt). Methionine oxidation and protein N-terminal acetylation were set as variable modifications; cysteine carbamidomethylation was set as fixed modification. The digestion parameters were set to “specific” and “Trypsin/P”. The minimum number of peptides and razor peptides for protein identification was 1; the minimum number of unique peptides was 0. Protein identification was performed at a peptide spectrum matches and protein false discovery rate of 0.01. The “second peptide” option was on. Successful identifications were transferred between the different raw files using the “Match between runs” option. Label-free quantification (LFQ) (Cox et al, 2014) was performed using an LFQ minimum ratio count of two. LFQ intensities were filtered for at least two valid values in at least one genotype, and missing values were imputed from a normal distribution with a width of 0.3 and downshift of 1.8. Analysis of the label-free quantification results was performed using R (R Development Core Team, 2010). MitoCarta annotations were added using the corresponding Gene names (primary) entry and the first of the Gene names (synonym) entries of the oldest UniProt ID with the highest number of peptides in the column “Protein IDs”. Only mitochondrial proteins, according to MitoCarta, were used for analysis. Protein label-free intensities were normalized using vsn (Huber et al, 2002). Differential expression analysis was performed using the two-sided moderated t-test from the limma package (Ritchie et al, 2015). Exploratory data analysis was performed using ggplot and GGally.

**Statistical methods**

Data were statistically analyzed using GraphPad Prism 8 software (except proteomics data as detailed above). Neither randomization...
nor blinding was implemented for animal studies and data analysis. All data are presented by means ± SEM. When two groups were compared, a two-sided unpaired Student’s t-test was used, while a one-way ANOVA and Tukey’s post hoc analysis were used for multiple group comparison. Mito-QC data are presented as 5–95% percentile boxplot, and non-parametric Mann–Whitney test was used for statistical analysis. Genotype distribution in mice and embryos was analyzed using chi-square test by comparing the obtained percentages against the expected Mendelian percentages. P-values < 0.05 were considered statistically significant. The exact number of replicates and P-values for each figure are summarized in Appendix Table S3.

## Data and software availability

The datasets produced in this study are available in the following databases: Mass spectrometry datasets have been deposited to the ProteomeXchange Consortium (Perez-Riverol et al., 2019): PRIDE PXD18639 (http://www.ebi.ac.uk/pride/archive/projects/PXD18639).

**Expanded View** for this article is available online.

## Acknowledgements

This study was supported by grants to NGL from the Swedish Research Council (2015-00418), the Knut and Alice Wallenberg Foundation, the European Research Council (Advanced Grant 2016-741366), the Swedish Cancer Society (2018.062), and the Swedish state under the agreement between the Swedish government and the county councils, the ALF agreement (SLL 2018.0471). AWr was supported by the Swedish Research Council (VR2016-02179). RWT is supported by the Wellcome Centre for Mitochondrial Research (203105/Z/16/Z), the Medical Research Council (MRC) International Centre for Genomic Medicine in Neuromuscular Disease, the Mitochondrial Disease Patient Cohort (UK) (G08000674), the Lily Foundation, the UK NIHR Biomedical Research Centre for Ageing and Age-related disease award to the Newcastle upon Tyne Foundation Hospitals NHS Trust, the MRC/EPSCR Molecular Pathology Node, and the UK NHS Highly Specialised Service for Rare Mitochondrial Disorders of Adults and Children (http://www.newcastle-mitochondria.com/). Mass spectrometric analyses and database searches for protein identification and quantification in mouse tissues and cultured cells were carried out at the Proteomics Biomedicum core facility, Karolinska Institutet, Stockholm, with an outstanding support by Dr. Akos Vegvari. We would like to thank Avan Taha and Dr. Xinping Li for performing proteomic sample preparation of mouse mitochondria and mass spectrometric measurements at the proteomics core facility at the Max Planck Institute for Biology of Ageing, Cologne, Germany. We thank Christian Kukat, Alexandra Just, and Anna-Lena Schumacher of FAC5 and Imaging Core Facility at Max Planck Institute for their assistance with histology experiments. We thank Rolf Wibom for measurements of respiratory chain enzyme activities. We thank Dr. Ian Ganley for the kind gift of the pBabe mito-QC vector. The authors are grateful to Prof. Nico Dantuma, Dr. Olle Sangfelt, and Dr. Javier Calvo-Garrido for productive discussions and useful advice.

## Author contributions

DA, OL, and N-GL conceived the project, designed the experiments, and wrote the manuscript. DA and OL performed and interpreted the majority of the experiments. DA, OL, CK, and N-GL advised on methodology and interpreted the data. AS, IA, and MJ performed experiments and analyzed the data. FS contributed to proteomic data analysis. AWe, RWT, and AWr provided critical input for the project. N-GL supervised the project. All the authors commented on the manuscript.

## Conflict of interest

The authors declare that they have no conflict of interest.
