### **Conflict of interest**

100 DP, TK and JW received unrestricted research grants from Echosens, Paris France and TK participated in a clinical advisory board meeting. MS was an Echosens scientific employee in the R&D department, but contributed in her role as scientist and author of papers in this meta-analysis. Echosens provided the FibroScan® device to Antoine-Béclère hospital, but the authors CSV, GP and SN did not receive funding from the manufacturers for carry out their research. VW served as a consultant and speaker for Echosens. No other authors have conflicts of interest.

### **105 Detailed Funding including original data sources**

110 This project is supported in part by the German Federal Ministry of Education and Research (BMBF, FKZ 01EO1001). The company Echosens provided funding, but did not influence study design and was not involved in data analysis. Data collection at Odense University Hospital received support from Innovation Fund Denmark, the Challenge Grant “MicrobLiver” grant number NNF15OC0016692 from the Novo Nordisk Foundation and the European Union’s Horizon 2020 research and innovation programme for “GALAXY” grant agreement number 668031. Data collection at the Federal University of Rio de Janeiro received support from the National Council for Research and Technology – CNPq, Brazil. QMA is a Newcastle NIHR Biomedical Research Centre investigator. PNN was supported by the National Institute of Health Research (NIHR) Birmingham Biomedical Research Centre (BRC). The views expressed are those of the authors and not necessarily those of the NHS, the  
115 NIHR or the Department of Health.

### **Author Contributions**

DP, VB, JW, TK: study concept and design, collected data from participating centres, data review and analysis, interpretation of data, drafting of the manuscript, statistical analysis, obtained funding  
120 Remaining authors: drafting of protocol, coded and provided data, interpretation of data, critical revision of the manuscript

### **Registration**

## **RESEARCH IN CONTEXT**

### **Evidence before this study**

Original research and meta-analyses showed that non-invasive grading of hepatic steatosis with the ultrasound based controlled attenuation parameter (CAP) is accurate over a variety of aetiologies when using the so-called M probe. A limitation of this probe is that it is not appropriate for patients with obesity meaning that the important application to non-alcoholic fatty liver disease (NAFLD) was limited. Recently, the XL probe was introduced, which was designed for patients with higher body mass index (BMI). A number of studies were conducted using CAP with the XL probe and showed promising results for steatosis grading compared to the histological gold-standard. Consensus regarding optimal cut-offs was not available and uncertainties in diagnostic performance and relevant covariates led us to conduct an individual patient data meta-analysis. In a systematic literature search, we identified 16 studies with histology-controlled CAP including the XL probe. We were able to obtain individual data from 13 of them and 2346 patients were included in the final analysis.

### **Added value of this study**

The diagnostic performance and optimal cut-offs for CAP with the XL probe depend substantially on aetiology, diabetes status, BMI and sex. The area under the curve (AUC) from receiver operating characteristic (ROC) analysis is only 0.754 and 0.717 for detection of higher grade steatosis (S2-3 or S3, respectively) in NAFLD patients. The AUC for detection of any steatosis (S1-3) is better at 0.819, but S0 cases are heavily influenced by patients scheduled for bariatric surgery. Overall, the diagnostic performance of CAP in bariatric surgery patients is better than for the average NAFLD patient. Previously proposed reliability criteria do not lead to improved performance. Comparison of M and XL probe measurements in overweight patients where both probes are viable shows high variance for the difference between measurements though the mean difference is small.

### **Implications of all the available evidence**

The interpretation of CAP must take aetiology and covariates into account. Even with the XL probe, CAP cannot grade steatosis in patients with NAFLD adequately. The findings in this study should be taken into account when developing or interpreting non-invasive diagnosis of NASH with methods that include CAP. Its value in a NAFLD screening setting needs to be studied, ideally with methods beyond the traditional histological reference standard.

## SUMMARY

### 155 **Background**

Diagnostic tools for liver disease now include estimation of steatosis (S0-S3) and controlled attenuation parameter (CAP) is one such non-invasive candidate. It has become available for obese patients (FibroScan XL probe), but consensus is lacking regarding cut-offs and its diagnostic performance. This individual patient data meta-analysis aims to assess diagnostic properties and identify relevant covariates.

### 160 **Methods**

Sixteen studies reported histology-controlled CAP including the XL probe, and individual data from 13 papers and 2346 patients were included. Probe recommendation was based on automated selection, manual assessment of skin-to-liver-capsule distance and a body mass index (BMI) criterion. Receiving operating characteristic methods and mixed models were used to assess diagnostic properties and covariates. Patients with non-alcoholic fatty liver disease (NAFLD) were analysed separately because of their predominant requirement for use of the XL probe (registration: CRD42018099284).

165

### **Findings**

Patients (age 46±14 years) were recruited from 20 centres in nine countries (29%, 23% and 47% were normal weight, overweight and obese respectively; 54%, 18%, 12% and 13% had NAFLD, viral hepatitis, alcohol associated liver disease and other aetiologies). The XL probe was recommended in 1050 patients, 930 of whom (89%) had NAFLD, and the areas under the curve were 0.82 (S0 vs S1-3; 95% CI 0.77 to 0.87) and 0.75 (S0-1 vs S2-3; 95% CI 0.72 to 0.79). CAP was independently affected by aetiology, diabetes, BMI, aspartate transaminase and sex. Optimal cut-offs differed substantially across aetiology.

170

### **Interpretation**

CAP cut-offs vary according to aetiology, and effectively recognize significant steatosis in patients with viral hepatitis. CAP cannot grade steatosis in patients with NAFLD adequately, but its value in a NAFLD screening setting needs to be studied, ideally with methods beyond the traditional histological reference standard.

175

### **Funding**

Supported in part by the German Federal Ministry of Education and Research and Echosens, which provided funding, but did not influence study design or analysis.

180

## INTRODUCTION

Fatty liver, the hepatic manifestation of the metabolic syndrome, has grown to become a major field of clinical research, and the development of fast and easily applicable non-invasive methods for assessment of fatty liver disease is of great importance.<sup>1</sup> Both serum-based markers and liver stiffness measurement (LSM) have evolved to become established and valuable tools to assess the degree of hepatic fibrosis.<sup>1,2</sup> More recently, non-invasive quantification of hepatic steatosis has attracted scientific interest and the continued development of technologies will help define the clinical implications of steatosis.<sup>3-7</sup> Magnetic resonance imaging (MRI) methods permit precise estimation of total hepatic fat, which is of value in clinical studies,<sup>8</sup> but is not ideal for the screening of large populations at risk.<sup>9</sup> On the other hand, the ultrasound-based controlled attenuation parameter (CAP) technology allows estimation of hepatic fat content during LSM with vibration-controlled transient elastography (VCTE) on the FibroScan equipment (Echosens, France).<sup>10</sup> CAP was originally available only with the M probe (appropriate for lean subjects and skin-to-liver-capsule distance (SLD) of less than 25 mm) and discriminates fairly well between histological grades of steatosis in patients with viral hepatitis and NAFLD, as shown in an individual patient data meta-analysis (IPDMA) performed by our team.<sup>11</sup> The CAP algorithm later introduced for the XL probe facilitates steatosis assessment in obese patients (SLD  $\geq$  25 mm), where steatosis assessment is most needed. Several biopsy controlled studies have assessed correlation of XL-CAP with histological steatosis grades, especially in obese patients with non-alcoholic fatty liver disease (NAFLD).<sup>12-27</sup>

The availability of both probes may provide the practitioner with the necessary tools to grade steatosis quickly and non-invasively in patients at risk, as recently demonstrated in one multi-centred prospective study on patients undergoing liver biopsy for suspicion of NAFLD or non-alcoholic steatohepatitis (NASH).<sup>14</sup> However, an in-depth meta-analysis considering all relevant covariates and reliability criteria is lacking, which is necessary to account for cohorts with mixed aetiology and broader inclusion criteria. Moreover, larger cohorts are needed to evaluate diagnostic performance and ascertain whether or not cut-offs established with the M probe are appropriate for the XL probe, especially considering that the M probe may have been used inappropriately in overweight patients.<sup>28</sup> The introduction of the XL probe is intended to open up the CAP field to obese patients, where steatosis quantification is most relevant. To assess its performance and provide a comprehensive comparison with the M probe, our research team performed an extensive IPDMA from studies that included use of the XL probe.

## METHODS

210 This study was approved by the ethics committee of the coordinating site in Leipzig (218/15-ek) and the study protocol was registered before start of the data analysis (Prospero CRD42018099284).

### *Search strategy and study selection*

Search terms and time intervals were defined at two consensus meetings of the study group in Paris 2018 and Vienna 2019. Only published or accepted English language manuscripts by a peer-reviewed journal until April 215 30th 2019 qualified for inclusion in the meta-analysis. Study results published only in abstract form were not considered.

Publications on the diagnostic properties of CAP for liver steatosis quantification with histology as reference standard were extracted from electronic databases from their inception until April 30 2019 including “PubMed” and “Web of Science”. The systematic literature search was performed using the term “controlled attenuation 220 parameter XL”. The final query for PubMed was: "controlled"[All Fields] AND "attenuation"[All Fields] AND "parameter"[All Fields] AND "XL"[All Fields] AND "english"[Language] NOT "review"[Publication Type] AND 1900/1/1:2019/4/30[Date - Entry]. An analogous query was used for Web of Science. Titles and abstract were screened for eligibility by two authors (TK and VB). In case of disagreement, a third researcher (DP) was consulted to arrive at a consensus. The articles selected for a full text review were examined by two researchers 225 (TK, DP) to determine whether or not the inclusion/exclusion criteria were met.

In addition to this search strategy, we screened abstract books of the International Liver Congress (EASL, 2016-2019) and The Liver Meeting (AASLD, 2016-2018) using the same search terms as above. The corresponding authors were contacted and invited to participate in the meta-analysis if their full papers were accepted within the pre-defined time limit.

### 230 *Inclusion and exclusion criteria*

Studies reporting original biopsy-controlled data of CAP for non-invasive grading of steatosis were eligible for inclusion in the IPDMA. CAP for the VCTE XL probe, which became commercially available in 2014, had to be included in the paper. Histology specimens must have been evaluated for steatosis according to the percentage of hepatocytes involved.<sup>29</sup> Approval of the local ethics committee was required and had to be forwarded on to the 235 analysis team. Studies that selected patients based primarily on the result of a CAP measurement were not included in the IPDMA to avoid selection bias. Studies were also excluded if data could not be obtained despite

multiple attempts to contact the study investigators. If individual data sets were published repeatedly, only the latest data set was used.

#### *Individual data verification and study quality assessment*

240 The quality of each study was appraised by two authors (VB and TK for half the articles and VB and DP for the other half) using the “Quality Assessment of Diagnostic Accuracy Studies 2” (QUADAS 2)<sup>30</sup>. Discrepancies were discussed and resolved by these three authors. As an important further test of data quality and to ensure that they were correctly interpreted, individual data from each study were used to reproduce the main results. Inconsistencies were communicated to the corresponding authors of the studies and resolved via discussions and  
245 revised data sets, as necessary.

#### *Steatosis grading and fibrosis staging*

Histopathological data were used as reference standard for the evaluation of CAP. Steatosis was defined according to the number of affected hepatocytes: S0 (<5%), S1 (5–33%), S2 (34–66%), S3 (>66%).<sup>29</sup> Fibrosis was staged according to the Metavir (for viral hepatitis) or NAFLD Activity Score (NAS) (for NAFLD and  
250 alcoholic liver disease (ALD)).<sup>29,31</sup> Quality criteria for the histological specimens (i.e. number of portal tracts and length of specimen) differed between studies, however, the risk of sampling variability is low for steatosis grading.<sup>32</sup> We therefore excluded only samples that were classified as unreliable by the respective study pathologist. Because the steatosis grade can be modulated by lifestyle and medical interventions, individual patients were excluded if the time interval between biopsy and CAP measurement was >6 months, as stipulated  
255 in the protocol and ratified at the study group meetings mentioned above.

#### *Vibration-controlled transient elastography including CAP measurement*

CAP acquisition took place in all studies during LSM with the VCTE device Fibroscan in line with recent guideline recommendations.<sup>2,33</sup> Cases with at least 10 single measurements for calculation of the CAP median were required. The manufacturer recommends using SLD at the measuring site for choice of the appropriate  
260 probe and has incorporated an automated probe selection software in the latest model of the device. However, different methods of probe selection have been proposed<sup>2,33</sup> and were expected amongst the studies. Therefore, we used an approach to define “correct” probe choice based on availability of data. These were automated probe selection, manual assessment of SLD, but also a body mass index (BMI) criterion proposed in international guidelines (cut-off: 30 kg/m<sup>2</sup>).<sup>2</sup> If anthropometric data indicated a high risk of inappropriate probe application,

265 the respective cases were excluded from the primary analysis: For the XL probe, extreme cases with BMI < 18 kg/m<sup>2</sup> were not considered, and M probe was not accepted in cases with BMI > 35 kg/m<sup>2</sup> unless the probe was selected by the internal software algorithm or SLD was <25 mm.<sup>34</sup> In all analyses of diagnostic performance, the data from the correct probe were always used. Following recommendations on the interpretation of LSM data for fibrosis estimation,<sup>35</sup> reliability criteria for CAP based on the interquartile range (IQR) of the single CAP  
270 measurements have recently been proposed: Wong et al.<sup>36</sup> suggested an IQR-threshold >40 dB/m for poorly reliable measurements with the M probe, whereas Semmler et al.<sup>37</sup> reported the relation of CAP-IQR/median of <0.1, <0.2, and <0.3 as a reliability indicator for both M and XL probe. We therefore analyzed the ability of these criteria to identify reliable CAP measurements.

### *Objectives*

275 The primary objective was to establish optimal cut-offs distinguishing mild ( $\leq$ S1) from advanced steatosis (S2-S3) for the XL probe and healthy (S0) from affected (S1-3) patients, if the number of S0 patients was sufficiently high. Secondary objectives were to (i) estimate the probability of a given steatosis grade at any specific CAP value, (ii) estimate the effects of covariates on CAP values, (iii) examine the use of established cut-offs, (iv) compare M and XL probes and (v) evaluate CAP quality criteria.

### 280 *Statistical methods*

All analyses were performed using the software R, version 3.6.1. Receiver operating characteristic (ROC) analyses including area under the curve (AUC) made use of the package “OptimalCutpoints” and the cut-off found using the median Youden optimum from a bootstrap method with 10,000 samples.<sup>38</sup> For comparison with the literature, the rule-in/rule-out optimal cut-offs were chosen by requiring that their respective sensitivity (rule-  
285 in)/specificity (rule-out) be 0.9. Confidence intervals for variables based on proportions were constructed using Wilson score intervals<sup>39</sup> and for the optimal cut-points, sensitivity and specificity from the quantiles of the bootstrapping samples. As stipulated in the protocol, a linear mixed model for CAP values included steatosis grade, BMI, diabetes status, sex, choice of probe and aetiology as covariates and the study as a random term and confidence intervals were determined with a profiling method.<sup>40</sup> These models were compared using ANOVA to  
290 the analogous fixed model (without study or with study as a fixed term). This permitted assessment of heterogeneity between studies from the variance of the random term, the coefficients in the study terms of the fixed effects model and the difference in the remaining coefficients between models with and without study terms. Ordinal regression from the “MASS” package<sup>40</sup> is used to estimate the probability of each steatosis grade

295 at a given CAP value after sampling the largest possible number of patients from the data with a prescribed prevalence of steatosis grades. Comparison of the M and XL probes was carried out with Bland-Altman methods. Two suggestions for CAP quality criteria were evaluated, one suggesting that the interquartile range (IQR) of 10 CAP measurements be smaller than 40 dB/m<sup>36</sup> and the other that the ratio of IQR to the median value be below 0.1, 0.2, or 0.3<sup>37</sup>. These criteria were examined using the linear correlation coefficient between CAP and histologically determined percentage of affected hepatocytes at different quality thresholds.

## 300 RESULTS

### *Papers and Patients*

**Figure 1** shows that the original search yielded 78 papers of which 16 met the study criteria; see **Supplementary table 1** for details about the studies. We were able to correspond with authors from all papers, but three did not provide data because of concerns on the part of the funding US agency regarding data sharing.

305 The remaining 13 papers comprised 2664 patients, 2346 of whom met the inclusion criteria for the current analysis (88%). Note that due to overlapping patients, two papers are listed in the following only as Chan 2018.<sup>22,26</sup> Two papers provided more than 300 patients, six between 100 and 200 and the remaining four under 100 patients. CAP was performed within one day of the reference test in 1717 (73%) and within one month in 2292 (97%) patients.

310 Patient characteristics can be found in **Table 1** and an assessment of the quality of the studies according to QUADAS-2<sup>30</sup> can be found in **Supplementary figure 1** and shows that the risk of bias was relatively low, but that patient selection and conduct of the index test could have introduced bias when applied to our research question.

Of note is the high proportion of patients with NAFLD (54%) and subjects with high BMI, many of whom were 315 candidates for bariatric surgery. However, in the NAFLD cohort, only 14% of the patients had a BMI greater than or equal to 45 kg/m<sup>2</sup>. Interestingly, 96/1277 (13%) patients with NAFLD were classified as S0, 72 of which were being considered for bariatric surgery and 17 came from a screening setting. There was a high prevalence of significant fibrosis ( $F > 1$ , 42%) which was unevenly distributed between those patients with (38%) and without NAFLD patients (48%). Among the former, those with S0 did not have advanced fibrosis. Note that the 320 LSM values in Table 1 based on the M and XL probes cannot be compared, since they derive largely from different patients.

**Table 1:** Population characteristics. ALD = Alcoholic liver disease; ALT = alanine transaminase; AST = aspartate aminotransferase; BMI = body mass index; CAP = controlled attenuation parameter; NAFLD/NASH = Nonalcoholic fatty liver disease / nonalcoholic steatohepatitis

	All patients (n=2346)	S0 (n=750)	S1 (n=623)	S2 (n=501)	S3 (n=472)

The results of ROC analyses are provided in **Table 2** by aetiology and for the XL probe alone in patients with NAFLD. Only data from the correct probe according to the definition in the Methodology section were included. For the XL probe in patients with NAFLD, the optimal cut-off to distinguish S0-1 from S2-3 was 317 dB/m (95% CI 306 to 334) and only marginally higher compared to the value of 310 dB/m, found in the total cohort of patients with NAFLD for which the XL probe was used in 73% of patients. Notably it was substantially higher than for patients with viral hepatitis, ALD or other aetiologies. Note that all but 15 of the patients with ALD came from a single study,<sup>41</sup> but that the Youden optimization chosen in **Table 2** complements other choices in that paper, which was optimized to have sensitivity/specificity of 0.9. The optimum cut-off in patients with ALD for S0 vs S1-3 was paradoxically higher than for S0-1 vs S2-3 (274 vs 268 dB/m), but the confidence intervals were wide (over 50 dB/m) and the shifts in sensitivity and specificity suggests that their sum remained fairly constant over a large range of CAP values. The large differences between aetiologies demonstrate that they must be considered separately in many analyses. For some analyses, we choose to focus on NAFLD, which is where the XL probe is most relevant, cf. the proportion of XL probe use according to aetiology in **Table 2**.

**Supplementary table 2** shows the diagnostic performance in NAFLD patients undergoing bariatric surgery vs non-bariatric patients and in those with BMI above and below 30 kg/m<sup>2</sup>. The distribution of steatosis grades depends on cohort type and diagnostic performance tends to be better in the bariatric cohorts, but relevant differences vanish when distinguishing by BMI, though optimal cut-offs may be affected. The correct probe choice in the NAFLD cohort is a matter of some debate, and moreover the penetration depth of even the XL probe can be a limiting factor in morbidly obese patients.<sup>13,42</sup> In **Supplementary tables 3 and 4** we provide the diagnostic performance using the manufacturer’s recommendation for probe choice and find analogous results, e.g. for the NAFLD cohort, optimal cut-offs are within one dB/m.

**Table 2:** Diagnostic properties of CAP for assessing histologically defined steatosis grade as estimates (95% confidence intervals). Only data from the correct probe choice were included. If the available data were too scant, then estimates were not provided, e.g. only 4 patients with “other” aetiologies had S3. AUC = Area under the curve; CAP = Controlled attenuation parameter; HBV = Hepatitis B virus; HCV = Hepatitis C virus; NAFLD = Non-alcoholic fatty liver disease.

	S0 vs S1-3	S0-1 vs S2-3	S0-2 vs S3
NAFLD XL probe (n=930, 95% BMI > 30 kg/m <sup>2</sup> )			
AUC	0.819 (0.769 to 0.869)	0.754 (0.720 to 0.787)	0.717 (0.684 to 0.751)

Specificity	0.659 (0.599 to 0.718)	—	—

If instead of the Youden cut-off approach, the sensitivity is set at 0.9, then the optimum in NAFLD patients is 267, 286 and 297 dB/m for S0 vs S1-3, S0-1 vs S2-3 and S0-2 vs S3 respectively. The values for specificity at these optima are 0.500, 0.394 and 0.344 respectively. If the specificity is set at 0.9, optimal cut-off values are 331, 372 and 385 dB/m for S0 vs S1-3, S0-1 vs S2-3 and S0-2 vs S3 respectively with commensurate sensitivities of 0.520, 0.255 and 0.224.

The diagnostic performance in patients with NAFLD using two sets of established cut-offs with and without adjustment of CAP values for aetiology, diabetes and BMI according to a previous suggestion derived from M-probe data can be found in **Supplementary table 5**.<sup>11,14</sup> The cut-offs taken from an IPDMA with mixed aetiology and the M-probe result in sensitivities above 0.9, but very poor specificities ranging from 0.25 to 0.42. Even NAFLD derived cut-offs do not lead to satisfactory sensitivity and specificity, the range being from 0.57 to 0.74. Adjusting CAP values, but retaining the aforementioned IPDMA cut-offs, leads to sensitivity and specificity roughly comparable to those found with NAFLD derived cut-offs.

Using ordinal regression, it is possible to estimate the probability for steatosis grade at a given CAP value, **Figure 2**. Such probabilities are closely related to PPV and NPV and depend strongly on prevalence. In some prevalence scenarios taken from the papers in this analysis, there are CAP values for which three or even all four steatosis grades are probable and distinction between them is therefore poor.

370 *Diagnostic performance across studies*

Although one works with individual patient data in an IPDMA, it cannot be treated as a single study. To assess potential study effects, we present areas under the curve, which are independent of cut-offs, between the original sources of our data and the pooled result from this IPDMA, **Figure 3**. The figures were recalculated using only the patients included in this IPDMA and a standardized optimization Youden method. There is substantial  
375 variation between studies and increasing NAFLD prevalence relative to the other liver diseases tends to lead to poorer diagnostic performance.

*Probe Choice and Relation to Aetiology*

The device offers two probes (M and XL), which can either be selected manually or by an automated probe selection software implemented in the most recent version of the device. The study designs considered here  
380 foresaw automated choice of probes for 895 patients (4 studies), use of both probes for 511 patients (5 studies), based on BMI for 443 patients (1 study), based on SLD for 421 patients (2 studies) and only used the XL probe for 76 patients (1 study). However, in some cases, if the selected probe failed, then the other one was used. The XL probe was correctly chosen according to our definitions in 1050 patients and the M probe in 1289 patients including 20 cases with BMI > 35 kg/m<sup>2</sup> but appropriate SLD. For seven patients, the correct probe choice could  
385 not be determined since BMI was unavailable.

Note that essentially all correct XL measurements were made on NAFLD patients (930/1050, 89%). In contrast to the previous IPDMA <sup>11</sup>, steatosis grade S0 was dominated by aetiologies other than NAFLD (654/750, 87%) whereas all other aetiologies were underrepresented for S1-S3 (415/1596, 26%), **Supplementary figure 2**.  
Notably, 75% of the NAFLD cohort with S0 (72/96 patients) were bariatric surgery patients.

390

*Covariates affecting CAP including the choice of M or XL probe*

The M and XL probes are designed for different anthropometric phenotypes based on skin-to-liver-capsule distance and therefore a direct comparison of their properties is clinically relevant in patients for whom either probe is conceivable. Moreover, such a comparison in all patients sheds light on the diagnostic and technical  
395 differences between the probes. CAP values from both probes were available in 527 patients (58% NAFLD). A Bland-Altman plot in **Supplementary figure 3** shows that there is little bias (4.4 dB/m) and essentially no dependence on the mean CAP value over a wide range of BMI values. However, the typical discrepancy between

the M and XL probe in a given patient is large (the mean absolute difference is 30 dB/m and a 95% predictive interval ranges from -78 to 82 dB/m at a mean CAP value of 250 dB/m).

400 For all patients, the correct probe (M or XL) was also included as a covariate in a linear mixed model in which study was the random term. The results of this multivariate analysis are provided in **Table 3** and show that CAP values for patients with steatosis differ by about 30, 62 and 81 dB/M from those without for S1, S2 and S3 respectively. Aetiology, BMI, sex, aspartate transaminase (AST) and diabetes also play a role, but the effect of probe choice is small. The standard deviation of the random term is 10.3 dB/m with a residual of 46.5 dB/m and  
 405 an ANOVA indicates that it differs significantly from a linear model without the random term ( $p < 0.001$ ), indicating that differences between studies are not negligible despite inclusion of covariates. However, estimates do not change by much in a linear model with study as a fixed effect despite accounting for steatosis grades, and although the term study is significant as a whole ( $p < 0.001$ ), no single study differs significantly from the arbitrarily chosen reference study. Similar results are found in patients with NAFLD alone, except that AST is no  
 410 longer identified as a relevant or significant covariate (**Supplementary table 6**). If one adjusts the CAP value in NAFLD patients by 10 dB/m for diabetics and males and by 2.6 dB/m per BMI point above/below 25 kg/m<sup>2</sup> up to a maximum of 50 kg/m<sup>2</sup>, then AUC changes from 0.807 to 0.826 (S0 vs S1-3), 0.736 to 0.762 (S0-1 vs S2-3) and 0.711 to 0.702 (S0-2 vs S3).

**Table 3:** Estimates and confidence intervals are shown from the fixed terms in a mixed model with CAP value as the dependent variable and study as a random term. The estimates describe how each variable is associated with the CAP result, even after accounting for the others. For example, patients with diabetes will have CAP values an average of 13.6 dB/m higher, even after accounting for aetiology steatosis grade, BMI, sex, ALT and AST. ALD = alcoholic liver disease; ALT = Alanine transaminase; AST = Aspartate transaminase; BMI = Body mass index; CAP = Controlled attenuation parameter; CI = Confidence interval; HBV = Hepatitis B virus; HCV = Hepatitis C virus; NALFD/NASH = Non-alcoholic fatty liver disease/ Non-alcoholic steatohepatitis.  
 415  
 420

	Estimate (dB/m)	95% CI (dB/m)
Intercept	239	219 to 259
Steatosis (S0 is reference)		
S1	30.4	24.2 to 36.8
S2	62.1	55.1 to 69.4
S3	81.0	73.6 to 88.5
Aetiology (ALD as reference)		
HBV	-17.2	-34.8 to 0.2
HCV	-18.2	-35.6 to -0.8
NAFLD/NASH	0.6	-16.2 to 17.4
Other	-20.6	-37.7 to -3.5
XL compared to M probe	6.5	-0.5 to 12.6
BMI (per kg/m <sup>2</sup> increase compared to 25 kg/m <sup>2</sup> )	2.57	2.11 to 2.97
Diabetes	13.6	8.7 to 18.8
Sex (male vs female)	12.0	7.7 to 16.4
ALT (per doubling of value)	1.06	-2.07 to 4.34
AST (per doubling of value)	-3.81	-7.46 to -0.29

For some patients, the M and XL probes may both be viable alternative choices, i.e. when penetration depth is close to the cross-over from the M to the XL probe. Unfortunately, SLD was unavailable in data sets for which  
425 both probes were used. Hence we consider NAFLD patients with  $23 < \text{BMI} < 30 \text{ kg/m}^2$ , in which more than half (56%) had a discrepancy, when steatosis category are allocated using the cut-offs from **Table 2**. There is a differences of at least two categories in 27/135 (20%) cases, **Supplementary table 7**. The M-probe yielded the correct result in 33/135 (24%) and the XL probe in 37/135 cases (27%).

#### 430 *Reliability criteria in NAFLD patients*

Diagnostic properties could be affected by unreliable measurements. If the threshold  $\text{IQR} > 40 \text{ dB/m}$  is used, then 32% of measurements are defined to be unreliable. However, the correlation between CAP and percentage hepatocytes does not improve, changing only from 0.452 in the former to 0.449 in the latter case, see **Supplementary figure 3a**. If instead the threshold is based on IQR/median, then 3%, 11% and 46% are deemed  
435 unreliable for cut-off of 0.3, 0.2 and 0.1 respectively. In fact, the analogous correlations become worse as the “reliability” criterion is made more stringent ( $r=0.436, 0.399$  and  $0.337$  respectively, see **Supplementary figure 3b**). Hence, we were not able to find evidence that any cut-off value provided value in improving performance.

## DISCUSSION

440 This comprehensive IPDMA on the diagnostic capabilities of CAP including the XL probe for non-invasive grading of hepatic fat found that diagnostic properties depend substantially on aetiology. Higher grades of steatosis in patients with NAFLD could not be distinguished reliably for individual patients and the areas under the curve for the XL probe were 0.82, 0.75 and 0.72 with optimal cut-offs at 297, 317 and 333 dB/m for >S0, >S1 and >S2 respectively. Mean CAP values from the available M and XL double measurements in a given  
445 patient were similar although the variation between them was high, resulting in misclassification of 50% of NAFLD cases (**Supplementary figure 3**). Diagnostic accuracy did not improve by applying proposed reliability criteria.<sup>36,37</sup> After adjusting for steatosis grade, we verified that CAP depended significantly on aetiology, diabetes and BMI and found moreover that CAP for males is about 13 dB/m higher than for females. Unexpectedly, diagnostic performance in bariatric surgery patients was somewhat better, which may in part be  
450 due to highly standardized recruitment and procedures as well as large biopsy samples.

Although our quantitative results agree on the whole with the published literature (cf. Figure 4), the picture that emerges when the results are viewed in this pooled fashion is new and the conclusions we draw are different. Individual studies suggest that the diagnosis of steatosis in NAFLD with CAP works well with the XL probe in obese patients, i.e. that the AUC for S0 vs S1-3 is high. However, some of these studies contain cohorts with  
455 mixed aetiologies in which S0 is dominated by non-NAFLD patients.<sup>15,16,21</sup> Others are pure NAFLD cohorts, but with a small number of S0 patients.<sup>13,14,18,23,26</sup> The definition of NAFLD formally excludes S0 so that their occurrence merits further consideration. In our data, S0 patients come either from studies with bariatric surgery cohorts<sup>13,18,23</sup> where histology is routinely obtained during surgery and irrespective of liver disease severity, or they come from a screening scenario where the majority of S0 patients were ultimately classified as non-  
460 NAFLD.<sup>14</sup> Notably, the S0 NAFLD cases did not have advanced fibrosis suggestive of burnout NASH. Because the S0 group is small and atypical, the important clinical question: “can steatosis be detected by CAP in a screening setting for subjects at risk for NAFLD” cannot be answered adequately with currently available data. Our group conducted a previous IPDMA on M probe CAP and found good results, with AUCs ranging from 0.82 to 0.88.<sup>11</sup> The data were restricted to “leaner” subjects (BMI > 35 kg/m<sup>2</sup> was an exclusion criterion) with M  
465 probe measurements and were dominated by viral hepatitis. Moreover, there were almost no S0 patients classified as having NAFLD and diagnostic properties for this aetiology alone could not be provided. An early conventional meta-analysis did treat diagnostic properties in NAFLD, but looked mainly at M probe data despite

many obese subjects and concluded that diagnostic capabilities should be viewed with caution.<sup>43</sup> Only two of the nine studies considered there used the XL probe and thus qualified for the current analysis and only one could be included. Our current data also suggest the need to be cautious with CAP for steatosis grading in NAFLD even if the XL probe is used, with AUCs of 0.75 (S0-1 vs S2-3) and 0.72 (S0-2 vs S3), cf. Table 2.

In the current meta-analysis, patients with viral hepatitis tended to have higher BMIs compared to our original IPDMA<sup>11</sup> because of the availability of the XL probe. The low prevalence of high-grade steatosis and relatively small total numbers meant that diagnostic performance could not be analysed in great depth for this aetiology. AUC was slightly lower here for S0 vs S1-3 compared to the previous IPDMA (0.77 vs 0.82), whereas it was comparable for S0-1 vs S2-3 (0.85 vs 0.86). Patients with ALD in the current paper had a fairly high prevalence of obesity (20%) despite infrequent use of the XL probe (8%), but they derived almost exclusively from a single study<sup>25</sup>, suggesting that more data in this aetiology are needed.

There has been some debate about optimal cut-offs and how they may depend on aetiology, probe (M vs XL) and anthropometry.<sup>11,14,26,44,45</sup> Considering the different penetration depths of the probes, it is essential to distinguish between two types of comparison: (i) between two probes used in a given patient where such data are available, in which case small mean differences were found of less than 10 dB/m<sup>26,44,46</sup> and (ii) between probes each used in the appropriate cohort (majority of data), in which case large differences in cut-offs are found unless models correct for anthropometry and co-morbidities. Here we can confirm both observations, but conclude that the small differences between the probes can be neglected if the correct probe is used. The choice of cut-off then may benefit from corrections for aetiology, diabetes and BMI as recommended in,<sup>11</sup> which for NAFLD in the current paper would lead to a shift from e.g. 280 dB/m (S0-2 vs S3) to about 330 dB/m, which is close to 337 dB/m as found by Eddowes et al.<sup>14</sup> Without such corrections, sensitivity is very high, but specificity is extremely low. Other authors have already noted that corrections do not necessarily improve AUC or other markers of overall diagnostic performance.<sup>26,37</sup> Corrections do however lead to a shift toward more equal balancing between sensitivity and specificity that could be relevant if both ruling in and ruling out steatosis are of interest. When only one of the two is the diagnostic goal, then it is typical to optimize based on either sensitivity or specificity of say 0.9, see e.g. Eddowes 2019.<sup>14</sup> For a specificity of 0.9, this can lead to extremely high cut-offs, which are no longer of clinical use. In the context of NAFLD, the current analysis suggests that adjustments may have the potential to improve AUC slightly, but this requires validation.

It is interesting to speculate as to what physiological mechanism could affect CAP measurements in diabetic patients after taking BMI, sex and other covariates into account. There is evidence that microvesicular steatosis is related to progression of NAFLD<sup>47</sup> meaning that it may be more prevalent among diabetes patients.<sup>48</sup> Since small fat droplets lead to more signal attenuation, this may lead to higher CAP values. Furthermore, diabetes patients may have a greater prevalence of steatohepatitis, which could also affect CAP. Such considerations could also be relevant in explaining aetiology specific differences. Beyond physiological mechanisms, the very different prevalence of steatosis depending on aetiology leads to different optimal cut-offs in ROC analyses.

The non-invasive quantification of hepatic fat requires critical appraisal since its clinical implications are a matter of ongoing debate.<sup>49</sup> Although fat accumulation in hepatocytes is considered a key mechanism in the natural history of fatty liver disease, long-term observational studies have not found that the histological degree of steatosis correlates with clinical endpoints, e.g. Angulo et al.<sup>50</sup> This finding challenges the need for estimating hepatic fat, but associations have been found between liver fat and progression of fibrosis<sup>51</sup> and between liver fat and metabolic syndrome, even after adjusting for NASH.<sup>52</sup> Moreover, current outcome data are biased due to the need for an invasive reference standard and fairly small sample sizes compared to blood pressure in cardiology, for example. Furthermore, liver fat assessed by histology refers to a proportion of affected cells by surface area, whereas MRI and CAP consider other conceptual notions that still require appropriate long-term observation of liver fat.<sup>9</sup> In addition, the value of serial assessment of liver fat quantification remains to be defined for prognosis and treatment efficacy of intervention.<sup>7</sup>

Another potential clinical benefit for CAP can be in identifying the small proportion of NAFLD candidates with S0 who ultimately turn out to have alternative diagnoses as shown in Eddowes et al.<sup>14</sup> Studies focusing on screening cohorts cannot use liver biopsies as a reference standard, but could use MRI, which is very sensitive to hepatic fat.<sup>8</sup> Up to now only a few studies have compared both MRI and CAP with histology with a modest sample size<sup>20,53,54</sup> or without S0 patients,<sup>55</sup> but all of them concluded that MRI outperforms CAP. Such studies can also address the value of continuous tests for steatosis severity, which is not possible with traditional steatosis grading. However, the clinical availability and costs of MRI, imply that combinations of screening tools need to be considered.<sup>9</sup>

The data presented here suggest that CAP could well be of epidemiological value, but raise questions about what role it could play in the GP's toolbox. Previous analyses have shown good diagnostic performance in hepatitis patients using the M probe<sup>11</sup>, and the current analysis suggests only a slight deterioration when extending the

525 population to patients with higher BMI and use of the XL probe. However, it is of limited diagnostic value for grading steatosis in obese NAFLD patients, which emphasizes inherent technical limitations of this ultrasound-based steatosis quantification. Using CAP, ultrasound signal attenuation is not exclusively induced by hepatocellular lipid droplets but is also related to subcutaneous tissue and abdominal wall<sup>56</sup> properties which become especially relevant in patients with metabolic risk factors and may explain our observations.

530 Despite such considerations, CAP still represents the first highly standardized and evaluated approach using ultrasound signal modulation for steatosis quantification. Technical modifications of CAP such as special algorithms for extremely obese patients<sup>13</sup> could improve diagnostic precision. In addition, further developments by other manufacturers utilize two-dimensional B-mode image control of the target region, which enhances performance in pilot studies and merit further evaluation.<sup>57,58</sup>

535 Strengths of our analysis are that it relies on the largest comprehensive database on biopsy controlled CAP measurements and that the mean time interval between the index (CAP) and reference tests (biopsy) is very short. The data derive from many expert international groups with only small differences between studies. The large number of paired XL and M probe measurements in overweight patients without *a priori* indication for one or the other facilitated important comparisons between the two. This first pooling of the available NAFLD  
540 patients exposed the fact that an considerable proportion of this population derives from bariatric surgery, but not from a typical screening target population and should be complemented in new studies.

A general weakness of studies with invasive reference standards is the so-called “verification bias”, see e.g. O’Sullivan et al.<sup>59</sup> It is incorrect to believe that sensitivity and specificity estimated from a complete case analysis are unbiased compared to a population without (indication for) biopsy, which again underscores the  
545 need for CAP screening studies with MRI as the reference standard. The high prevalence of significant fibrosis illustrates that indication for biopsy was based on the suspicion of advanced liver disease in many of the patients. Moreover, bariatric surgery patients are recruited with less emphasis on liver disease and tended to have fewer “grey zone” patients with S1 and S2 so that their diagnostic performance was better. This may also hold for screening populations of interest without indication for liver biopsy. A related issue is the spectrum effect,  
550 describing a dependence on sensitivity and specificity with regard to patient characteristics.<sup>60</sup> This can induce spectrum bias if populations are selected based on such characteristics and results are generalized to a different target population and this may explain in part the non-negligible difference between studies. The QUADAS 2 assessment showed that there is some potential for bias as a result of patient selection and precise use of the

index test. These are expected to be small compared to the verification and spectrum biases, however, when CAP  
555 is used in a screening population. A specific limitation of this IPDMA is that we could not include data from the  
US NASH Clinical Research Network because of rigid federal NIH restrictions.<sup>17,20,27</sup> However, these studies in  
total are expected to have supplied data from about 300 patients (Supplementary table 1) and only about 20 with  
S0. Given the somewhat worse diagnostic performance in Table 4 of Siddiqui 2018, this lack of data can be  
560 expected to bias our results slightly toward optimistic estimates. It is not feasible in an intercontinental  
diagnostic IPDMA to obtain central histological readings. However, since steatosis is known to have good inter-  
and intra-observer agreement, in contrast to other NASH parameters,<sup>32,61</sup> this is likely only to have led to a small  
bias, if any. The choice of correct probe in the studies analysed here did not always follow the manufacturer's  
recommendations and the effect of this on performance would be interesting, but was not possible in this  
IPDMA given the nature of the data. Future studies should firmly adhere to the recommendations. Finally, the  
565 strict definition of NAFLD precluding concomitant diseases could be inherently problematic since it neglects  
metabolically driven processes in liver disease of other aetiology. A recent proposal for a revision of the  
definition of metabolic liver disease addresses this issue, but was not available in the current data set.<sup>62</sup> Such  
considerations could also be relevant for patients with viral hepatitis and concomitant fatty liver disease.

This analysis completes a decade of CAP research for the grading of steatosis, but does not focus on recent  
570 advancements for the detection of steatohepatitis, which combine CAP with LSM and AST and may be useful  
for guiding medical intervention in the future.<sup>63</sup> However, the imprecision of CAP-based steatosis grading,  
especially when important covariates are left unconsidered, sheds light on the capabilities of non-invasive NASH  
detection. This highlights the necessity for several independent studies with a variety of designs.

In conclusion, CAP cut-offs vary according to aetiology, and effectively recognize significant steatosis in  
575 patients with viral hepatitis. CAP values alone relative to rigid cut-offs provide little clinically valuable  
information for grading steatosis in patients with NAFLD despite use of the XL probe. Based on a subset of the  
data, the difference between M and XL probe values in a given patient may be large, but their mean difference in  
a given population is quite small. Current data on S0 in the context of NAFLD are scant and heavily influenced  
by bariatric surgery, so that firm conclusions on diagnostic performance cannot yet be drawn. Knowledge of  
580 prevalence and covariates may help interpret CAP use and the application in screening scenarios requires further  
research beyond the traditional histological reference standard.

## FIGURE CAPTIONS

750 **Figure 1:** Flowchart of the papers and patients included in the final analysis including probe data availability. The letters 'i' and 'n' represent the number of studies and patients respectively. CAP = controlled attenuation parameter.

755 **Figure 2:** Probability of steatosis grade as a function of controlled attenuation parameter (CAP) for non-alcoholic fatty liver disease (NAFLD) patients. The prevalence of each grade (S0–S3) is shown in brackets. The choice for each panel is based on the observed values from: (a) Eddowes 2019,<sup>14</sup> (b) Naveau 2017,<sup>23</sup> (c) Chan 2018,<sup>26</sup> (d) Baumeler 2019,<sup>15</sup> respectively.

760 **Figure 3:** The areas under the curve from the current analysis and the papers that comprise its data are ordered by aetiology. Note that Lai only contributed 26 patients not in the Chan paper. Cardoso 2019 had no S0 patients. ALD = Alcoholic liver disease; IPDMA = Individual patient data meta-analysis; NAFLD = Non-alcoholic fatty liver disease; ROC = Receiver operating characteristics.

Footnote to Figure 3

\*In Eddowes 2019, only patients with suspected NAFLD were included. In 30 of 47 S0 patients, another diagnosis was established.
